

# Building a Bayes Linear Emulator

This document complements the code provided in the GitHub repository <https://github.com/dario-domi/Bayes-Linear-Emulation>. It illustrates the components which a Bayes Linear Emulator of a function  $f$  comprises of, and details the meaning of all optional arguments of the R function `BL.Emul()` in the repository: the latter is available to download, for the user to build their own emulator in research tasks.

## Setting

Let  $f: U \rightarrow \mathbb{R}$  be a function,  $U \subseteq \mathbb{R}^m$ . Suppose  $f$  is slow to evaluate<sup>1</sup>. We thus want to build a fast surrogate of  $f$ , which we call an **emulator** of  $f$ . The emulator will provide instantaneous predictions of the value  $f(x)$  for any  $x \in U$ , and determine the level of uncertainty associated with the prediction.

The process behind the construction of an emulator consists of two main steps:

1. Make prior specifications about  $f$  (*e.g.*, mean behaviour, smoothness, *etc.*).
2. Adjust these in light of the observed values of  $f$  at a small, fixed set of inputs  $\mathcal{D} = \{x^{(1)}, \dots, x^{(n)}\} \subset U$ .

The emulator built by the R function `BL.Emul()` relies upon the *Bayes Linear* statistical approach<sup>2</sup>: informally, this means that only second-order specifications (mean, variances and covariances) about  $f$  are required, which are then *adjusted* once the values  $f(x^{(1)}), \dots, f(x^{(n)})$  are observed.

---

<sup>1</sup>Typically,  $f(x)$  is the output of a computer model, simulating the dynamics of a complex system when values of the system parameters have been set to  $x$ . Evaluating  $f(x)$  may be both slow and computationally intensive.

# 1 Model of the BL Emulator

In order to build an emulator  $\tilde{f}$  of  $f$ , we assume the following form for  $f$ :

$$f(x) = \sum_{j=1}^q \beta_j g_j(x_{[A]}) + \eta(x_{[A]}) + \varepsilon(x), \quad x \in U. \quad (1)$$

$x_{[A]} \in \mathbb{R}^p$  are called **active inputs**: they are identified as a subset of  $p \leq m$  coordinates of  $x \in \mathbb{R}^m$ , responsible for most of the variation of  $f$  across the domain  $U$ . The three terms in (1) are as follows:

1. The **regression term**  $\beta^T g(x_{[A]})$  is a linear combination of  $q$  known basis functions  $g_j(x_{[A]})$ , *e.g.*, polynomials in the components of  $x_{[A]}$ .  $\beta \in \mathbb{R}^q$  are unknown coefficients, for which second-order prior specification can be made.
2. The **term**  $\eta(x_{[A]})$  is a zero-mean stochastic process, with prior covariance function modelled as:

$$\text{Cov}[\eta(x_{[A]}), \eta(x'_{[A]})] = \sigma_\eta^2 k(\|x_{[A]} - x'_{[A]}\|_{\mathbf{d}}). \quad (2)$$

The **kernel**  $k(\cdot)$  is a function of a scalar quantity  $r \geq 0$ , in (2) this being a norm of the difference between the two active inputs  $x_{[A]}$  and  $x'_{[A]}$ . The norm depends on a set of **correlation lengths**  $\mathbf{d} = (d_1, \dots, d_p)$ .

The role of the correlation lengths and classical choices for  $k$  available within `BL.Emul()` are discussed in [subsection 1.1](#). The kernel  $k$  satisfies  $k(0) = 1$ , hence the quantity  $\sigma_\eta^2 \geq 0$  represents the variance of  $\eta(x_{[A]})$  at any  $x_{[A]}$ .

3. The **nugget term**  $\varepsilon(x)$  accounts for the small portion of variability in  $f$  explained by the inactive inputs (residual variability). It is modelled as a zero-mean stochastic process, with  $\text{Var}[\varepsilon(x)] = \sigma_\varepsilon^2$  and  $\text{Cov}[\varepsilon(x), \varepsilon(x')] = 0$  if  $x \neq x'$ .

We denote the sum of the first two terms in (1) by  $f^*(x_{[A]})$ , so that equation (1) reads

$$f(x) = f^*(x_{[A]}) + \varepsilon(x). \quad (3)$$

Given the above specifications and the values of  $f$  at the set  $\mathcal{D} = \{x^{(1)}, \dots, x^{(n)}\}$  of **design points**:

$$F = (f(x^{(1)}), \dots, f(x^{(n)}))^T,$$

the Bayes Linear framework allows to *adjust* the prior model for  $f^*(x_{[A]})$  to the observed values in  $F$ , at any  $x_{[A]}$ .

This means that an emulator  $\tilde{f}^*$  of  $f^*$  can be built, which provides, at any  $x_{[A]}$ , the adjusted mean and variance of  $f^*(x_{[A]})$  in light of the observed  $F$ :

$$\mathbb{E}[\tilde{f}^*(x_{[A]})], \quad \mathbb{V}\text{ar}[\tilde{f}^*(x_{[A]})]. \quad (4)$$

The interested reader can find the formulas and derivation of the expressions in (4) in Section\*\*\*. Once these are obtained, expectation and variance of an emulator of  $f$  (in which we are ultimately interested), at an input  $x$  with active inputs  $x_{[A]}$ , follow from the relation (3) linking  $f$  and  $f^*$ :

$$\mathbb{E}[\tilde{f}(x)] = \mathbb{E}[\tilde{f}^*(x_{[A]})] \quad (5)$$

$$\mathbb{V}\text{ar}[\tilde{f}(x)] = \mathbb{V}\text{ar}[\tilde{f}^*(x_{[A]})] + \sigma_\varepsilon^2. \quad (6)$$

The function `BL.Emul()` returns the values in (5) and (6) at any sequence of  $N$  inputs  $x_{[A]}$  passed to the function.

**Computational Note:** The function is optimised for speed, as well as memory: it will run smoothly even for very large  $N$ , as long as there is enough RAM space to handle the  $2N$  floats returned as outputs.

## 1.1 Covariance Kernel and Correlation Lengths

This section provides a guide to the kernels  $k(\cdot)$  available in `BL.Emul()` (see equation (2)), simple heuristics to help choose between them, and the role of correlation lengths in specifying the prior covariance of  $\eta$ .

Given a vector  $\mathbf{d} = (d_1, \dots, d_p)$  with  $d_i > 0$ , the square of the norm in (2) is computed as follows:

$$\|x_{[A]} - x'_{[A]}\|_{\mathbf{d}}^2 = \sum_{i=1}^p \left( \frac{x_{[A],i} - x'_{[A],i}}{d_i} \right)^2, \quad x_{[A]}, x'_{[A]} \in \mathbb{R}^p, \quad (7)$$

where  $x_{[A],i}$  denotes the  $i$ -th component of  $x_{[A]} \in \mathbb{R}^p$ . The effect of  $d_i$  is therefore to scale distances along coordinate  $i$ : the smaller  $d_i$ , the “more distant” the two vectors  $x_{[A]}$  and  $x'_{[A]}$  will appear along coordinate  $i$ .

Once  $r = \|x_{[A]} - x'_{[A]}\|_{\mathbf{d}}$  is evaluated, the prior correlation between  $\eta(x_{[A]})$  and  $\eta(x'_{[A]})$  is computed as  $k(r)$  where  $k$  is one of the kernels described below. In all cases,  $k$  is a decreasing function of  $r \geq 0$  with  $k(0) = 1$ . Hence, higher values of the correlation lengths in  $\mathbf{d}$  yield higher prior correlations between the various  $\eta(x_{[A]})$ .

While the values of  $\mathbf{d}$  affect the strength of correlations in the outputs of  $\eta$ , the specific choice of the kernel  $k$  will affect the regularity of  $\eta$ , and may therefore be made in light of knowledge/beliefs on the regularity of the function  $f$  to be emulated. The following choices for  $k$  are available in `BL.Emul()`:

- Squared-Exponential

$$k(r) = \exp(-r^2), \quad r \geq 0. \quad (8)$$

A process  $\eta$  with the above covariance kernel is infinitely many times differentiable.

- Matérn 5/2

$$k(r) = \left(1 + \sqrt{5}r + \frac{5}{3}r^2\right) \exp(-\sqrt{5}r), \quad r \geq 0. \quad (9)$$

A process  $\eta$  with the above covariance kernel is twice differentiable.

- Matérn 3/2

$$k(r) = (1 + \sqrt{3}r) \exp(-\sqrt{3}r), \quad r \geq 0. \quad (10)$$

A process  $\eta$  with the above covariance kernel is differentiable.

- Absolute Exponential

$$k(r) = \exp(-r), \quad r \geq 0. \quad (11)$$

A process  $\eta$  with the above covariance kernel is continuous but not differentiable.

All four previous regularity results hold both pathwise and in mean-square.

## 2 Table of Inputs of `BL.Emul()`

[Table 1](#) lists all arguments of the function `BL.Emul()`, their size/type, and the meaning of each argument in reference to the above setting. Default values of all optional arguments are also listed.

**Table 1:** Description of all inputs to the function `BL.Emul()`. Notation as in [section 1](#). Design points:  $x^{(i)}$ ,  $i = 1, \dots, n$ . Test points (where to evaluate the emulator):  $\tilde{x}^{(i)}$ ,  $i = 1, \dots, N$ . The default value for correlation length  $d_j$  is computed as a third of the maximum difference between the  $j$ -th components of any two design points.

| Variable (X)         | Size         | Description   | Optional? | Default                     |
|----------------------|--------------|---|-----------|-----------------------------|
